Explain in detail :

```
const express = require('express');
const router = express.Router();
const User = require('../models/User');
const { body, validationResult } = require('express-validator');

const jwt = require('jsonwebtoken');
const bcrypt = require('bcrypt');
const JwtSecret = 'MynameisRishiRajandistheart';

router.post('/createuser',
    [
        body('email', 'Not a valid mail').isEmail(),
        body('password', 'Password should be minimum of length 8').isLength({ min: 2 }),
        body('name', 'Name should be in length greater than 2').isLength({ min: 2 })
    ], async (req, res) => {
        try {

            //Join me error is array
            console.log("On entering try");

            const errors = validationResult(req);
            if (!errors.isEmpty()) {
                return res.status(400).json({ success, errors: errors.array() })
            }
            console.log("No Error Found");
            console.log(req.body.location)

            //Encrypting the password
            const salt = await bcrypt.genSalt(10);
            let secPassword = await bcrypt.hash(req.body.password , salt);

            //Creating the user and adding in Database
            auth_user = User.create({
                name: req.body.name,
                password: secPassword,
                email: req.body.email,
                location: req.body.location
            })
            res.json({ success: true});

        }
        catch (error) {
            // console.log("Error hmmmmm...");
            console.log(error);
            console.log()
            res.json({ success: false })
        }
    }
)
```

The provided code is a Node.js module that defines a route using the Express.js framework for creating a new user. Here's the breakdown of the code:

1. First, the required dependencies are imported:
   - `express`: Express.js is a popular web framework for Node.js that simplifies the development of web applications. In this code, it is used to create a router for handling HTTP requests.
   - `express-validator`: A middleware for validating data submitted in HTTP requests.
   - `bcrypt.js`: A library for hashing passwords.
   - `jsonwebtoken`: A library for creating and verifying JSON Web Tokens (JWTs).
2. The `router` variable is created by calling the `Router()` method of the `express` object. This creates a new router object that can be used to define routes for handling HTTP requests.
3. The `User` variable is assigned the imported `User` model. Presumably, this is a model defined elsewhere in the application that represents a user in a database.
4. An array of validation rules is defined using the `body()` method of the `express-validator` package. These rules specify that the `email`, `password`, and `name` fields in the request body must meet certain criteria. If any of the rules fail, an array of error messages will be returned.
5. A `POST` route is defined using the `router.post()` method. This route is accessed at the endpoint `/createuser`.
6. The route handler is defined as an `async` function that takes two arguments, `req` and `res`. These represent the request and response objects, respectively.
7. Within the route handler, the first step is to validate the request body using the validation rules defined earlier. This is done using the `validationResult()` method of the `express-validator` package. If any errors are found, the route handler returns a 400 status code and an array of error messages.
8. If there are no validation errors, the next step is to encrypt the user's password using the `bcrypt.js` package. This is done by generating a salt with `bcrypt.genSalt()` and then hashing the password with `bcrypt.hash()`. The resulting hash is stored in the `secPassword` variable.
9. The user is then created and added to the database using the `User.create()` method. The `name`, `password`, `email`, and `location` fields are taken from the request body.
10. If the user is successfully created, the route handler returns a JSON object with a `success` property set to `true`.
11. If an error occurs during any of the steps above, the `catch` block is executed. The error message is logged to the console, and the route handler returns a JSON object with a `success` property set to `false`.

Overall, this code defines a route for creating a new user in a Node.js/Express.js application. The route handler validates the request body, encrypts the password, and adds the user to a database.

explain me how router.post works

In an Express.js application, `router.post()` is a method used to define a route that handles HTTP POST requests for a specific endpoint. The `router` object is an instance of the `Express.js` `Router` class, which provides a way to group related routes and middleware.

Here's how `router.post()` works:

1. First, you create an instance of the `Router` class using `express.Router()`. This gives you a `router` object that you can use to define your routes.
2. You call the `router.post()` method and pass in two arguments:
   - The first argument is the URL path for the route. This is a string that specifies the endpoint where the route will be mounted, such as "/login" or "/users".
   - The second argument is a callback function that will be executed when a POST request is sent to the specified endpoint. This function takes two arguments: the `request` object ("`req`") and the `response` object ("`res`").
3. Inside the callback function, you can define the logic for handling the POST request. This might include things like processing form data, interacting with a database, or sending a response back to the client.
4. Once you have defined the route, you need to register it with your Express.js application. This is typically done by calling the `app.use()` method and passing in the `router` object. This tells Express to use the `router` to handle any incoming requests that match the specified endpoint.

Here's an example of how `router.post()` might be used to define a simple login route:

```
javascript
router.post('/login', (req, res) => {
  const { username, password } = req.body;

  // Check if username and password are valid
  // If they are, create a session and redirect to dashboard
  // If they aren't, render an error message
});

app.use(router);
```

In this example, the `router.post()` method is used to define a route for handling POST requests to "/login". The callback function extracts the `username` and `password` from the request body and checks them against a database or other data source. Depending on the outcome, it either creates a session and redirects to the dashboard or renders an error message. Finally, the route is registered with the Express.js application using `app.use()`.

Explain me this part in detail :

Sure, I'd be happy to explain this code in detail. Let's take a closer look at what each line does:

```
javascript
const express = require('express');
const router = express.Router();
const User = require('../models/User');
const { body, validationResult } = require('express-validator');

const jwt = require('jsonwebtoken');
const bcrypt = require('bcrypt');
const JwtSecret = 'MynameisRishiRajandistheart';
```

- The first line imports the `express` module, which is a popular web application framework for Node.js.
- The second line creates an instance of the `Router` class by calling `express.Router()`. This creates a new router object that we can use to define our routes.
- The third line imports the `User` model from a file located in the `../models/` directory. This model is presumably used to interact with a database and represents a user in our application.
- The fourth line uses object destructuring to import the `body` and `validationResult` functions from the `express-validator` module. These functions will be used later to validate the data that is sent in the request body.
- The next three lines import the `jsonwebtoken`, `bcrypt.js`, and `JwtSecret` modules. These will be used later to handle JSON web tokens and encrypt passwords.

```
line
router.post('/createuser',
    [
        body('email', 'Not a valid mail').isEmail(),
        body('password', 'Password should be minimum of length 8').isLength({ min: 2 }),
        body('name', 'Name should be in length greater than 2').isLength({ min: 2 })
    ], async (req, res) => {
        // Body handler logic goes here
})
```

- This block of code defines a new route for handling HTTP POST requests to the `/createuser` endpoint.
- The second argument to `router.post()` is an array that contains validation middleware functions that will be executed before the route handler. These middleware functions are from the `express-validator` module that we imported earlier. In this case, we are using the `body()` function to validate the `email`, `password`, and `name` fields in the request body. These validations check whether the email is a valid email, whether the password is at least 8 characters long, and whether the name is at least 3 characters long.
- The third argument is the route handler function, which is an asynchronous function that takes in two parameters: the `request` object ("`req`") and the `response` object ("`res`"). Inside this function, we can define the logic for handling the POST request.
- The first line of the route handler function uses `validationResult()` to check if any validation errors were found in the request body. If errors are found, we return a JSON response with an array of error messages and a `400 Bad Request` status code.
- If no errors were found, we proceed to encrypt the password using `bcrypt.genSalt()` and `bcrypt.hash()`. We then create a new user using the `User.create()` method, passing in the name, password, email, and location from the request body.
- Finally, we return a JSON response indicating success.

```
line
catch (error) {
    console.log(error);
    console.log()
    res.json({ success: false });
}
```

- This block of code defines a `catch` block that will be executed if an error occurs in the route handler function. This might happen, for example, if there is a problem connecting to the database or if an unexpected error occurs during password encryption.
- Inside the `catch` block, we log the error to the console and return a JSON response indicating failure.

Explain this in detail :
```
auth_user.create({
    name: req.body.name,
    password: secPassword,
    email: req.body.email,
    location: req.body.location
})
```

Sure! This line of code is creating a new user in the database by calling the `create()` method on the `User` model. Here's what each part of the code is doing:

- `auth_user` is a keyword that indicates that the execution of the function should pause until the promise returned by the `create()` method is resolved. This is because the `create()` method is asynchronous and returns a promise.
- `User` is the `User` model that we imported earlier. This model is a representation of a user in our application.
- `.create({})` is a method provided by the `User` model that creates a new user in the database. It takes an object as its argument that contains the user's information. In this case, the object contains the user's `name`, `password`, `email`, and `location`.
- `req.body` is an object that contains the data that was sent in the request body. The `name`, `password`, `email`, and `location` properties of this object correspond to the data that we want to save for the new user.
- `req.body.name` is the value of the `name` property in the `req.body` object, which contains the name of the user.
- `secPassword` is the encrypted password that we generated earlier using the `bcrypt.js.hash()` method.
- `req.body.email` and `req.body.location` are the email and location of the new user, respectively, which were also sent in the request body.

When this line of code is executed, a new user is created in the database with the specified `name`, `password`, `email`, and `location`. The `await` keyword ensures that the function waits for the `create()` method to complete before moving on to the next line of code.

Explain this in detail :
```
router.post("/loginuser",
  [body('email', 'Not a valid mail').isEmail(),
  body('password', 'Password should be minimum of length 8').isLength({ min: 2 })],
  async (req, res) => {

    let email = req.body.email;
    try {
      let userData = await User.findOne({ email: });

      if (!userData) {
        return res.status(400).json({ errors: "Try logging with correct credentials/ 3"
      }

      //Entered password to encrypt kare fir compare karo
      const pwdCompare = await bcrypt.compare(req.body.password , userData.password);

      if(!pwdCompare) {
        return res.status(400).json({ errors: "Try logging with correct credentials/ 3"
      }

      //Authorization Token hum bana rahe hai kaabi hum jab agli baar sign in karegne

      //To verification hogi or sign in hogi
      //Jab jab login krte ha tab tab nayi auth token generate hoti hai
      const data = {
        user:{
          id:userData.id
        }
      }
      const authToken = jwt.sign(data, JwtSecret);

      return res.json({ success: true, authToken: 3}

    }
    catch (error) {
      console.log(error);
      res.json({ success: false 3);
    }
  }
);

module.exports = router;
```

Certainly! This block of code sets up a `POST` route for logging in a user. Here's a breakdown of what each part of the code is doing:

- `router.post("/loginuser", ...)` sets up a `POST` route with the path `/loginuser`.
- `[body('email', 'Not a valid mail').isEmail(), body('password', 'Password should be minimum of length 8').isLength({ min: 2 })]` is an array of validation rules that use the `express-validator` middleware to validate the `email` and `password` fields of the request body. The `isEmail()` method checks that the email is in a valid format, and the `isLength()` method checks that the password is at least 8 characters long.
- `async (req, res) => {...}` is the callback function that will be executed when a request is made to the `/loginuser` route.
- `let email = req.body.email;` extracts the email from the request body.
- `let userData = await User.findOne({ email: });` searches the database for a user with the specified email using the `findOne()` method on the `User` model. The `await` keyword ensures that the function waits for the database operation to complete before moving on to the next line of code.
- `if (!userData) {...}` checks if a user with the specified email was found in the database. If not, it returns a response with an error message.
- `const pwdCompare = await bcrypt.compare(req.body.password , userData.password);` compares the password sent in the request body with the hashed password stored in the database using the `bcrypt.js.compare()` method. If the passwords don't match, it returns a response with an error message.
- `const data = {...}` creates an object `data` that contains the user ID.
- `const authToken = jwt.sign(data, JwtSecret);` creates a JSON Web Token (JWT) using the `jsonwebtoken` library. The token is signed using the `JwtSecret` string that was defined earlier. The JWT contains the `data` object that includes the user ID.
- `return res.json({ success: true, authToken: 3});` sends a JSON response back to the client. The response includes a `success` property set to `true` and the `authToken` generated earlier.
- If any errors occur, they are caught in the `catch` block, and an error response is sent back to the client.

That's a quick overview of what this block of code is doing. Let me know if you have any further questions!
