What is Routes in Node

In Node.js, a route refers to the URL path and HTTP method combination that a server will respond to. Routes are used to map incoming requests to the appropriate handler functions that will generate the response.

Routes typically consist of a path and an HTTP method. For example, a route might be defined for the path "/users" and the HTTP method "GET", which would mean that when a client sends a GET request to the "/users" path, the server would respond with a list of users.

Node.js has several popular libraries for defining and handling routes, including Express.js, Hapi.js, and Koa.js. These libraries provide a simple and efficient way to handle HTTP requests and define the routes for the server to respond to.

Routes are an important aspect of building web applications in Node.js as they enable developers to create RESTful APIs and provide a structured way to organize and handle incoming requests.

Explain in Detail :-
const express = require('express');
const router = express.Router();

router.post('/vehicleData', (req,res)=>{

try{
console.log(global.VehicleData);
console.log(global.VehicleCategory);
res.send(global.VehicleData, global.VehicleCategory);
}
catch(error){
console.log(error.message);
res.send("Server Error");
}
});
module.exports = router;

The code snippet you have provided is an example of defining a route in Express.js. Here's what it does:

First, it imports the Express.js library using the `require` function and creates a new instance of the Express Router by calling the `Router` method.

```
const express = require('express');
const router = express.Router();
```

Next, it defines a POST route for the "/vehicleData" path by calling the `post` method on the router instance. This route will be triggered when a client sends a POST request to the "/vehicleData" path.

```
router.post('/vehicleData', (req,res)=>{
```

The second parameter of the `post` method is a callback function that will be executed when the route is triggered. This callback function takes two parameters - `req` and `res` - which represent the HTTP request and response objects, respectively.

Within the callback function, the code retrieves the global variables `global.VehicleData` and `global.VehicleCategory` and sends them as the response using the `send` method on the `res` object.

```
try{
res.send(global.VehicleData, global.VehicleCategory);
}
```

In case of an error, the code will catch the error and send a "Server Error" message as the response.

```
catch(error){
console.log(error.message);
res.send("Server Error");
}
```

Finally, the code exports the `router` instance so that it can be used in other parts of the application.

```
module.exports = router;
```

Overall, this code defines a POST route for the "/vehicleData" path that retrieves data from global variables and sends it as the response. If there is an error, it sends a "Server Error" message instead.

Rectify it
const express = require('express');
const router = express.Router();

router.post('/vehicleData', (req,res)=>{

try{
console.log(global.VehicleData);
console.log(global.VehicleCategory);
res.send(global.VehicleData, global.VehicleCategory);
}
catch(error){
console.log(error.message);
res.send("Server Error");
}
});
module.exports = router;

The code snippet you provided seems to be syntactically correct. However, there is a typo in the `catch` block where `error.message` is misspelled as `error.message`.

Here's the corrected code:

```
const express = require('express');
const router = express.Router();

router.post('/vehicleData', (req, res) => {
try {
console.log(global.VehicleData, global.VehicleCategory);
} catch (error) {
console.log(error.message);
res.send("Server Error");
}
});

module.exports = router;
```

Other than the typo, the code defines a POST route for the "/vehicleData" path that sends an array of data from global variables `global.VehicleData` and `global.VehicleCategory` as the response. If there is an error, it logs the error message to the console and sends a "Server Error" message as the response.

I am not able to see the VehicleData on my webpage

If you're not able to see the `VehicleData` on your webpage, there could be several reasons for this. Here are some things you can check:

1. Verify that the route is being called: Make sure that the route you defined in your Express.js app is being called by your webpage. You can check this by adding some console.log statements to your server-side code to see if the route is being hit.
2. Check for errors: Make sure there are no errors in your server-side code that might be preventing the `VehicleData` from being sent to the client. Check the console for any error messages that might be occurring.
3. Verify that the data is being sent: Make sure that the data you are trying to send is being sent correctly. You can check this by using a tool like Postman to make a request to your server-side route and verify that the data is being sent correctly.
4. Check your client-side code: Make sure that your client-side code is correctly handling the response from the server-side route. Check for any errors in your JavaScript code that might be preventing the `VehicleData` from being displayed on the webpage.
5. Make sure the data is formatted correctly: Make sure that the data you are sending is formatted correctly for your client-side code to display. If the data is in a format that your client-side code doesn't understand, it won't be able to display it correctly.

By checking these things, you should be able to identify the issue and figure out why the `VehicleData` isn't being displayed on your webpage.

const express = require('express');
const mongoDB = require('./db');// Importing a custom module that connects to MongoDB
const app = express();
const port = 5000;

// Setting headers to avoid CORS errors
//app.use(cors(), res, next) => { // Using headers to avoid CORS errors
app.use(function (req, res, next) { // Middleware to process requests from a specific origin (in this case, port 3000)
and sets the headers for the response
app.use(cors(), res, next) => {
res.setHeader("Access-Control-Allow-Origin", "http://localhost:3000");// Allow port or preset
render for rich tap
res.header(
"Access-Control-Allow-Headers",
"Origin, X-Requested-With, Content-Type, Accept"
);
next();
});
app.use(express.json())

// By mounting the CreateUser module on the /api path using app.use('/api',
require('./Routes/CreateUser'));
// any HTTP request that matches the /api path, such as GET /api/users or POST /api/users,
will be passed to the CreateUser module for handling.
app.use(express.json());
app.use('/api', require('./Routes/CreateUser'));
app.use('/api', require('./Routes/DisplayData'));
// app.use('related path', module)

app.get('/', (req, res) => {
res.send('Hello World!')
})

app.listen(port, () => {
console.log(' Example app listening on http://localhost:${port}`)
})

Will /DisplayData will be ever called?

Yes, the `/DisplayData` route can be called if a matching HTTP request is made to it.

In the code you provided, you are mounting the `DisplayData` module on the `/api` path using `app.use('/api', require('./Routes/DisplayData'))`. This means that any HTTP request that matches the `/api/DisplayData` path, such as `GET /api/DisplayData` or `POST /api/DisplayData`, will be passed to the `DisplayData` module for handling.

So, if you make an HTTP request to `http://localhost:5000/api/DisplayData`, the `DisplayData` module will be called and it will handle the request.

Explain each part in detail

const response = await fetch("http://localhost:5000/api/createuser", {

method: "POST",
headers: {
"Content-Type": "application/json"
},
body: JSON.stringify({ name: credentials.name, email: credentials.email, password:
credentials.password, location: credentials.address })
});

const json = await response.json();

console.log(json);
//console.log("kaise ho");
if (!json.success) {
//console.log("galat");
alert("Enter Valid Credentials");
}
else {
//console.log("sahi");
localStorage.setItem("authToken", json.authToken);
console.log(localStorage);
navigate("/");
}
});

const onChange = (e) => {
setCredentials({ ...credentials, [e.target.name]: e.target.value });
};

This is a code snippet written in JavaScript, most likely in the context of a React application. Let me break it down part by part:

```
const response = await fetch("http://localhost:5000/api/createuser", {
method: "POST",
headers: {
"Content-Type": "application/json"
},
body: JSON.stringify({ name: credentials.name, email: credentials.email,
password: credentials.password, location: credentials.address })
});
```

This code creates an HTTP request to the URL `http://localhost:5000/api/createuser` using the `fetch` function. The `method` option is set to `"POST"` because this is a request to create a new user in the database. The `headers` option is set to include a `Content-Type: application/json` header, indicating that the body of the request will be in JSON format. The `body` option is set to a JSON string representing an object containing the new user's details, which are taken from the `credentials` state object.

```
const json = await response.json();
```

This code reads the response from the HTTP request as a JSON object using the `json` method of the `response` object. This line of code is awaiting the completion of the HTTP request before proceeding, due to the use of the `await` keyword.

```
if (!json.success) {
//console.log("galat");
navigate("/login");
} else {
alert("Enter Valid Credentials");
}
```

This code checks if the response from the HTTP request contains a `success` property that is `true`. If it does, it logs the response object to the console, navigates to the `/login` page (presumably taking an authentication token to local storage), and otherwise shows an alert message saying "Enter Valid Credentials".

```
const onChange = (e) => {
setCredentials({ ...credentials, [e.target.name]: e.target.value });
};
```

This code defines an event handler function called `onChange` that is executed whenever the value of an input field changes. This function uses the `setCredentials` function to update the `credentials` state object, replacing only the property corresponding to the `name` attribute of the input field that was changed. This is accomplished using the spread syntax (`...`), `credentials` (to copy all of the existing properties of the `credentials` object, and then replacing the property specified by `[e.target.name]` with the new value from `e.target.value`.

Explain in Detail :-
const response = await fetch("http://localhost:5000/api/login", {

method: "POST",
headers: {
"Content-Type": "application/json"
},
body: JSON.stringify({ email: credentials.email, password: credentials.password})
});

const json = await response.json();

//console.log(
//console.log(success);
console.log(json);
//Turn local storage line save to cahe fun
localStorage.setItem("authToken", json.authToken);
console.log(localStorage.getItem("authToken"));
navigate("/");
}
else {
alert("Enter Valid Credentials");
}
});

This code snippet is responsible for making a POST request to the server's `/api/loginuser` endpoint and handling the response.

- `const response = await fetch("http://localhost:5000/api/loginuser",{...});`: This line creates the `fetch` function to make an HTTP POST request to the server's `/api/loginuser` endpoint. It passes an options object with the request method, headers, and body data. The `await` keyword is used to wait for the server to respond.
- `const json = await response.json();`: This line extracts the response data in JSON format and stores it in a `json` variable. The `await` keyword is used to wait for the response to be converted to JSON.
- `if (!json.success) {...}`: This line checks the `success` property in the JSON response. If it's `false` (the user has been successfully logged in), and the code inside the `if` block is executed. If it's `false`, an alert is displayed to the user, and the code inside the `else` block is executed.
- `localStorage.setItem("authToken", json.authToken);`: This line saves the user's authentication token in the browser's local storage. The token is retrieved from the JSON response using the `authToken` property.
- `navigate("/");`: This line navigates the user to the homepage of the web application using the `navigate` function from the `@reach/router` library. If the user was successfully logged in, they are redirected to the homepage.
- `alert("Enter Valid Credentials");`: This line displays an alert to the user if the `success` property in the JSON response is `false`. It informs the user that they have entered invalid credentials.
